Epidermal inclusion cysts of the breast

Abstract
Epidermal inclusion cysts are uncommon in the breast, but the consequences can be severe when these cysts occur in the breast parenchyma. Here, we report two such cases. The patient in case 1 was a 37-year-old woman with a 3-cm palpable mass in the right breast. Mammography revealed a round and smoothly outlined mass, which indicated a benign tumor, and sonography showed an irregularly shaped and heterogeneous hypoechogenic mass, fibroadenoma was suspected on the basis of clinical and image findings, but excisional biopsy revealed an epidermal inclusion cyst. The patient in case 2 was a 50-year-old woman with a 2.5-cm lesion in the left breast. Mammography revealed a round, dense, smoothly outlined mass, and sonography showed a well-defined, central hyperechogenic mass. Breast cancer was suspected on the basis of the sonographic findings and the age of the patient, but the resected specimen revealed an epidermal inclusion cyst. Although epidermal inclusion cysts are benign, occasionally they may play a role in the origin of squamous carcinoma of the breast. Mammographic and sonographic features of an epidermal cyst may mimic a malignant lesion. Malignant change appears to occur more frequently in epidermal inclusion cysts in the mammary gland, compared to common epidermal inclusion cysts, and this may be associated with origination of mammary epidermal inclusion cysts from squamous metaplasia of the mammary duct epithelium.

Epidermoid inclusion cyst of the breast is potentially serious, although such cysts are rare, and differentiation from a malignant or benign breast tumor is required. Excision is probably the most appropriate treatment, and can eliminate the possible risk of malignant transformation.

Keywords: epidermal inclusion cyst, epidermoid cyst, breast, cancer.

Introduction
An epidermal inclusion cyst lined by a cornified epithelium, has a distinct granular layer, and contains lamellated keratin without calcification. Such cysts most commonly occur on the scalp and in the skin of the neck and back, whereas they are only rarely found in other areas, including the skin of the breast; to date, fewer than 40 cases of epidermal inclusion cysts of the breast have been reported in the English-language literature [1-9]. Diagnosis is straightforward for epidermal inclusion cysts that occur in the breast subcutis as a small nodule, but enlarged cysts in the breast parenchyma require to be differentiated from malignant or benign tumors of the breast. This article two case of epidermoid cyst of breast were explored.
Case 1
An 37-year-old woman was referred to our hospital for investigation of a palpable mass in her right breast. She had been aware of the mass for about six months after delivery. Examination revealed a 3-cm lesion in the lower outer quadrant of the right breast. The lesion appeared to be round, firm, well-described and without adherent to the overlying skin. Mammography revealed a round, dense, smoothly outlined mass (Fig. 1), and sonography showed a well-defined, but irregularly shaped and heterogeneous hypoechoic mass measuring 45×30 mm. Samples obtained by fine needle aspiration lacked epithelial cells and could not be used for evaluation. Breast cancer was unsuspected on the basis of the sonographic findings and the age of the patient, and excisional biopsy was performed. The mass measured 3.5×3.5 cm and the cut surface revealed a cystic cavity filled with fragile, greasy and dark-brown material.

Pathologic examination revealed the cyst consisted of mature squamous epithelium and with the multiple layers of keratin, consistent with an epidermal inclusion cyst (Fig. 2-3).

Case 2
A 50-year-old woman was referred to our hospital for investigation of a mass in her right & left breast. The mass had persisted for 2 years and had history of hysterectomy due to uterine myoma three years ago also had lumpectomy in left breast two years ago and because of pain it diagnosed as fibroadenoma. Examination revealed a 2-cm lesion in the center of the right breast. The lesion appeared to be round, firm, well-described and partially attached to the skin in the lower half of the breast. Mammography revealed a round, dense, smoothly outlined mass measuring 2.5cm in the right breast and round masses 1*1 in left breast.

Sonography showed a well-defined, central hyperechoic mass measuring 3cm in the right breast and multiple cysts in both breasts. Fine needle aspiration samples of the main lesion revealed an absence of epithelial cells and a small amount of keratin. On the basis of the clinical and imaging findings, a phyllodes tumor or a giant fibroadenoma with hyaline degeneration was suspected. After excisional removal of mass, an epidermoid cyst was confirmed, and also in left breast fibroadenoma was confirmed again.

Discussion
Epidermal cysts in the breast are believed to
arise through several different mechanisms. First, they can develop from obstructed hair follicles. Second, they may result from trauma, such as reduction in mammoplasty or needle biopsy of the breast, which may cause torn fragments of the epidermis with the deep infiltration within the breast tissue [1-3]. Third, they can be generated by squamous metaplasia of normal columnar cells within an ectatic duct in an area of fibrocystic disease or in a fibroadenoma [4]. In our two cases, the pathogenesis of the epidermal inclusion cysts may have been due to obstruction of the hair follicles. There was no past history of breast biopsy or trauma in either case and both tumors were adherent to the overlying skin, with no episode of inflammation of the cyst in either case. Generally, the epidermal inclusion cysts that develop in the skin of the head and dorsal regions are macroscopically noted as the skin protrusions, which may be due to the firm composition of subcutaneous tissue such as bone and muscle in those regions. On the other hand, histologically flexible fat and mammary gland tissues are present under the breast skin, and this may explain why epidermal inclusion cysts that develop in the breast skin grow toward the deep subcutaneous tissue and are difficult to distinguish clinically from a mammary gland tumor. On mammography, an epidermal inclusion cyst appears as a well-circumscribed, homogeneous density and thus is distinguishable from breast cancer [5]. Even when the mammographic appearance of a palpable mass is consistent with a benign lesion, the finding of a solid lesion on sonography may require tissue diagnosis to exclude a carcinoma with well-defined borders, as in case 1. On sonography, the breast epidermal inclusion cysts have a solid, well-circumscribed and complex appearance; the specific sonographic features of these cysts were described by Pavel et al. as an onion-rings appearance with alternating concentric hyperechoic and hypoechoic rings, which correspond to the pathologic features of lamellated keratin [6].

Although epidermal inclusion cysts are benign, occasionally they may play a role in the origin of squamous carcinoma of the breast. Squamous cell carcinoma develops only rarely (0.045%) in the wall of common epidermal inclusion cysts [7]. Nonetheless, Menville et al. identified 36 cases of epidermal inclusion cysts of the breast out of a total of 3000 breast lesions, and found that 29 of these epidermal cysts were benign and 7 (19%) were malignant [8]. Willis and Hasleton also reported a possible role of epidermal inclu-
Epidermal inclusion cysts in the breast are rare, but a significant concern due to their potential for malignant transformation. These cysts are often associated with or originate from squamous metaplasia of the mammary duct epithelium, which may explain their increased risk of malignancy compared to common epidermal inclusion cysts. In the mammary gland, the incidence of malignant change appears to be higher, possibly due to the association with origination of mammary epidermal inclusion cysts from squamous metaplasia of the mammary duct epithelium.

In a search of the English-language literature, 12 cases of epidermal inclusion cysts were reported. These cysts typically appear as circumscribed, round or oval, isodense on high-density masses with a diameter of 0.8-10.0 cm; their appearance and mammographic findings support the diagnosis. Microcalcifications within these cysts have been noted, which can aid in their identification and differentiation from other breast lesions.

Inflammatory downward growth of the epidermis caused by an obstructed hair follicle on a pore has been postulated. Epidermal inclusion cysts can also result from trauma, with epidermal fragments being implanted more deeply. Genlock reported two cases of epidermal cysts associated with fine needle aspiration biopsy, and Fajardo and Bessen reported epidermal inclusion cysts that were resulted from reduction mammoplasty. In the United States, the technique generally involves repositioning of the nipple-areolar unit with infolding of a vascularized tissue pedicle, which can lead to the development of epidermal inclusion cysts after the procedure. The authors encountered three cases of epidermal inclusion cysts after reduction mammoplasty and describe the associated mammographic and sonographic characteristics.

In summary, an epidermal inclusion cyst of the breast is potentially serious, although such cysts are rare. Differentiation from a malignant or benign breast tumor is required. They may play a role in the origin of rare squamous carcinoma of the breast as suggested by Hasleton and colleagues. Clinically, they can mimic benign as well as malignant tumors. Excision is probably the most appropriate treatment, which eliminates the possible risk of malignant transformation.
