Received: 27 Aug 2016          Published: 26 Dec 2017

Abstract

Background: Type 2 diabetes is a growing public health problem and is associated with increased morbidity and mortality. The worldwide prevalence of type 2 diabetes is rising. Polyphenols, such as flavonoids, phenolic acid, and stilbens, are a large and heterogeneous group of phytochemicals in plant-based foods. In this review, we aimed at assessing the studies on polyphenols and diabetes management.

Methods: A literature search in the PubMed, EMBASE, Scopus, and ISI Web of Science databases was conducted to identify relevant studies published from 1986 to Jan 2017.

Results: Several animal models and a limited number of human studies have revealed that polyphenols decrease hyperglycemia and improve acute insulin secretion and insulin sensitivity. The possible mechanisms include decrease in glucose absorption in the intestine, inhibition of carbohydrates digestion, stimulation of insulin secretion, modulation of glucose release from the liver, activation of insulin receptors and glucose uptake in insulin-sensitive tissues, modulation of intracellular signaling pathways, and gene expression.

Conclusion: Growing evidence indicates that various dietary polyphenols may influence blood glucose at different levels and may also help control and prevent diabetes complication. However, we still need more clinical trials to determine the effects of polyphenols-rich foods, their effective dose, and mechanisms of their effects in managing diabetes.

Keywords: Polyphenol, Blood glucose, Inflammation, Phytochemical, Type 2 diabetes

Introduction

Type 2 diabetes (T2D), a growing public health problem, is associated with increased morbidity and mortality. According to the report of International Diabetes Federation (IDF), the number of people with diabetes in the world will increase from 382 million in 2013 to 592 million by 2035 (1). In Europe, approximately 6% to 8% of the population suffer from diabetes, of them nearly 90% have T2D, making T2D the fastest enhancing disease in Europe and worldwide (2). Inflammation is a serious problem in patients with diabetes and plays an important role in the evolution of atherosclerotic process in non-insulin dependent diabetes mellitus (NIDDM), together with the known influence of glucose and lipid metabolism pathology. Inflammation both increases the levels of circulating inflammatory cytokines and insulin resistance in the liver, skeletal muscles, and vascular endothelium (3).

Polyphenols are the most abundant antioxidants in the diet of humans. There are thousands of natural polyphenols in the plant kingdom (4). Polyphenols, such as flavonoids, phenolic acid, and stilbenes, are a large and heterogeneous group of phytochemicals in plant-based foods (tea, soy, coffee, cocoa, cereal grains, cinnamon, ginger, fruits, and berries). Polyphenols are classified into several categories based on the number of phenol rings and structural elements that bind these rings (4).

↑What is “already known” in this topic:
This research can be used by physicians, nutritionists, and diet therapists and by all people, especially those with diabetes and those suffering from insulin resistance, such as metabolic syndrome and polycystic ovary syndrome (PCOS).

→What this article adds:
The possible effect of polyphenol on diabetes management is already known, and this article adds to the previously known knowledge by summarizing the results of other researches on the effectiveness and mechanisms of polyphenols on diabetes management.
Growing evidence indicates that various dietary polyphenols may prevent diabetes. In this article, we will discuss some polyphenol-rich foods and their possible effect on blood glucose.

Curcumin

Curcumin is a natural compound extracted from the root of Curcuma Longa and is the main component of the Indian curry spice. Curcumin has been consumed in the traditional Asian medicine for centuries because of its anti-inflammatory properties. Curcumin has also antioxidant and anticarcinogenic effects (5-7). Its anti-cancer activity is mainly attributable to the inactivation of hypoxia-inducible factor-1 (HIF-1), as curcumin is known to downregulate HIF-1α (8) and HIF-1β (9) and inhibit downstream actions, e.g. angiogenesis mediated by HIF-1. Also, it is able to selectively kill tumor cells or prevent tumorigenesis through interfering with many cellular pathways (6, 10). It represses nuclear factor-kB (NF-kB), inhibits adiogenic transcription factors and the cell cycle, and induces apoptosis (11-13). In colorectal cancer, curcumin treatment upregulates p53 expression (14). It has been reported that curcumin inhibits TNF-α-induced expression of Interleukin-1 beta (IL-1β), IL-6, and tumor necrosis factor (TNF-α) in human keratinocytes. It enhances the secretion of adiponectin (15), inhibits insulin-regulated glucose transporter 4 (GLUT4) translocation and glucose transport (16, 17). Some studies demonstrate that 10–25 μM of curcumin efficiently inhibited the differentiation of mouse adipocytes. In concentrations of 10–50 μM, curcumin is able to activate AMP-activated protein kinase (AMPK)(18) and it can also inhibit the activation of MAPK pathway, c-Jun N-terminal kinases (JNK), p38MAPK, and extra- cellular signal-regulated kinases (ERK) in adipocytes (19). Thus, it stimulates proliferation (20) but suppresses lipid accumulation and adipogenesis (21). However, conflicting data on how curcumin affects peroxisome proliferator-activated receptors (PPARs) ranges from direct promotion to inhibition via AMPK (22-24). Interestingly, curcumin applied at a half maximal inhibitory concentration (IC50) of 45 μM can also interfere with cellular energy balance by inhibiting ATP synthesis at the mitochondrial membrane (25). Furthermore, it was illustrated that active spice-derived components such as curcumin suppress obesity-induced inflammatory responses in adipose tissue of obese mice. As a result, migration and release of monocyte chemoattractant protein-1 (MCP-1) and TNF-α were inhibited and MCP-1 was released from adipocytes (26). Beyond the anti-inflammatory properties, curcumin has also ameliorated diabetes in different mouse models; 200 mg curcumin/kg diet has improved insulin resistance and hyperglycemia in mice. Also, it elevated insulin level and lowered the free fatty acid, triglyceride, cholesterol, and glucose level in blood and reduced lipid oxidation (27). Further studies on curcumin has illustrated that it reduces macrophage infiltration into the white adipose tissue, induces the expression of adiponectin, and decreases NF-kB activity (28, 29). Administration of 500 mg/kg curcumin in diet leads to a decrease in body weight gain, adiposity, and expression of VEGF in mice (30). Anti-inflammatory and antidiabetic effects were also seen in rats (31, 32) and hamsters (33). Taken together, these data indicated that curcumin can repress inflammation and obesity and improve the chronic condition in diabetes.

An in vitro study found that curcuminoids effectively enhanced the phosphorylation of AMP-activated protein kinase (AMPK) and its downstream target acetyl-CoA carboxylase (ACC) in H4IE rat hepatoma and Hep3B human hepatoma cells with 400 times (curcumin) to 1000 times (tetrahydrocurcuminoids) the potency of metformin. These results suggest that AMPK mediated the suppression of hepatic gluconeogenesis and may be a potential mechanism mediating glucose-lowering effects of curcuminoids (34). In another study on 240 prediabetic adults, participants were given 250 milligrams of curcumin or a placebo every day for 9 months. After intervention, none of those taking curcumin developed diabetes, but 16.4% of the placebo group did.

group did. In other words, curcumin was 100% effective in preventing Type 2 diabetes (35). Table 1 demonstrates recent clinical trials testing curcumin with respect to diabetic and inflammatory markers.

**Resveratrol**

Resveratrol is a non-flavanoid polyphenol produced naturally by many plants including grapes, peanuts, cranberries, blueberries, and Japanese knotweed. The resveratrol content ranges from 50 to 100 μg/g in fresh grape skin and from 0.1 to 14 mg/l in red wine (44, 45). It is synthesized in plants in response to injury or fungal attack. Different studies have found that resveratrol has antioxidant and anti-inflammatory effects, ameliorating inflammation through countering with TNF-α-induced effects and declining mRNA expression and secreting different adipokines such as plasminogen activator inhibitor-1 (PAI-1), IL-1β, IL-6, IL-8, and MCP-1. Resveratrol and curcumin increase pancreatic β-cell function by inhibiting phosphodiesterase activity. They protect against β-cell dysfunction. In T2DM, cAMP plays an important role in glucose and insulin-stimulated insulin secretion as well as overall pancreatic β-cell health. A potential therapeutic target in managing T2DM is to regulate the activity of phosphodiesterases (PDEs), which degrade cAMP. Both resveratrol and curcumin have been reported to act as PDE inhibitors in various cell types, but it remains unknown whether they do so in pancreatic β-cells. Treating β-cell lines and human islets with these polyphenols has led to an increase in intracellular cyclic adenosine monophosphate (cAMP) levels. Resveratrol and curcumin increase pancreatic β-cell function through inhibiting phosphodiesterase activity and promote β-cell function across species by acting as direct PDE inhibitors in β-cells and islets. Treatment of mouse and human β-cells with resveratrol and curcumin resulted in a substantial reduction of PDE expression, particularly PDE3B, PDE8A, and PDE10A, which are known to be important in insulin signaling (46). Also, resveratrol and curcumin treatment showed a profound ability to directly inhibit PDE activity in β-cells of pancreas. As a result of PDE inhibition, resveratrol and curcumin treatment prevented the degradation of cAMP, leading to an increase in its intracellular levels. Subsequently, this allowed for activation of cAMP-dependent signaling pathways, augmenting insulin secretion and β-cell function (46).

Resveratrol effects on weight reduction induced by several mechanisms include increasing apoptosis, fat mobilization, fatty acids oxidation, lipolysis, and decrease in lipogenesis and adipogenesis. Table 2 displays an overview of recent clinical trials testing resveratrol with respect to diabetic and inflammatory markers.

**Cinnamon**

with Type 2 diabetes through improving the ability to respond to insulin. A total of 8 meta-analysis clinical studies demonstrated that cinnamon or cinnamon extracts decrease fasting blood glucose levels (51). Cinnamon slows the rate of stomach emptying after eating. In the study of Hlebowicz et al., participants ate a cup of rice pudding with and without a teaspoon of cinnamon. Adding cinnamon decreased the rate of stomach emptying from 37% to 34.5% and significantly decreased the rise in blood sugar levels at 0 and 120 minutes compared to ingestion of the reference meal. Even less than half a teaspoon a day reduced blood sugar levels of patients with type 2 diabetes (52).

**Capsaicin**

Capsaicin is an active component in chili peppers and is usually consumed as a spice, but it is also used for neurological disorders, such as diabetic neuropathy and tropical therapy of cutaneous allergy. Capsaicin specifically binds to ion channel, which is activated by several physical and chemical stimuli and causes pungent sensation in mammals (53). Moreover, studies illustrated that it can activate AMPK and suppress adipocyte differentiation in mouse adipocytes (54). In murine macrophages, capsaicin’s anti-inflammatory action was shown by repressing the expression of proinflammatory gene inducible nitric oxide synthase (iNOS). It also represses cyclooxygenase 2 (COX2) activity, inhibits prostaglandin E2 (PGE2) production, and inactivates NF-kB by inhibiting (IkBα) degradation (55). Also, it binds specifically to PPARγ and suppresses the production of TNF-α. Hence, capsaicin’s anti-inflammatory effect is assumed to be mediated through activation of PPARγ and NF-kB (56, 57). Screening different plant extracts also determined its potential to activate PPARα (58). In mouse adipocytes, capsaicin inhibits adipogenesis and decreases

es the amount of intracellular triglycerides. Thermogenesis is enhanced by capsaicin (59). Through stimulating lipolysis and thermogenesis, capsaicin increases the energy expenditure in adipose tissue (60). More recently, it has been shown that capsaicin induces concentration-dependent (0.1–10 μM) upregulation of the mitochondrial UCP-2 (uncoupling protein 2), a mitochondrial protein transporter that separates oxidative phosphorylation from ATP synthesis with energy dissipated as heat and other genes involved in lipid catabolism in white adipocytes (61). Another study on adipocytes revealed that activation of VR1 by capsaicin concentrations, starting from 10 nM, promotes a calcium influx and prevents adipogenesis and obesity, which has also been confirmed in vivo (62). This property of capsaicin likely explains the activation of further downstream targets. In earlier studies on rats, it has been shown that capsaicin stimulates lipid mobilization from adipose tissue and decreases the perirenal adipose tissue weight and serum triglyceride concentration if added to 0.014% of the diet (63). This was also associated with an increased energy metabolism and an enhanced respiratory quotient (64). More investigations in mice suggest that capsaicin suppresses obesity-induced inflammation by modulating adipokine release. Also, it suppresses the expression and secretion of IL-6 and MCP-1 from obese adipose tissues, but increases adiponectin gene expression. Intraperitoneal administration of capsaicin (2 mg/kg bw) suppresses macrophage activation and decreases the release of proinflammatory mediators and stops their migration (57, 65). Capsaicin also counteracts the proinflammatory effects of saturated fatty acids through reduction in JNK activity, thus it may be regarded as a beneficial phytochemical for attenuating obesity-induced inflammation and obesity-related pathologies. In some studies, an increased fat oxidation (66) and a lowered fat intake (67) were observed in overweight participants treated with capsaicin. More recent studies investigating the effect of dietary capsaicin showed an effect on glucose and insulin. Capsaicin also seems to be involved in the regulation of energy expenditure and activation of brown adipose tissue in humans (68).

Table 3 demonstrates recent clinical trials testing capsaicin with respect to diabetic and inflammatory markers.

### Catechins and Procyanidins

Catechins are flavanols that contain catechin (C), epicatechin (EC), gallo catechin (GC), epigallocatechin (EGC), and their gallates. Cocoa is very rich in catechins and flavanol-based oligomers known as procyanidins (76). Procyanidins positively affect inflammatory diseases, such obesity and Type 2 diabetes. They can modulate inflammation through decreasing the expression of IL-6 and MCP-1 and increasing the production of anti-inflammatory adipokine and adiponectin (77). Table 4 displays recent clinical trials testing catechin with respect to diabetic and inflammatory markers.

### Berberine

Berberine is a bitter compound found in the roots of several plants including goldenseal, barberry, and Oregon grape. Studies have found that berberine can lower blood glucose. Chinese researchers compared berberine with metformin in a pilot study on 36 participants. They found that berberine (0.5 g 3 times a day) decreased blood sugar level just as well as metformin in 3 months. Berberine also significantly reduced fasting blood sugar and after meal blood sugar of patients (99). In the same study, researchers gave berberine (0.5 g 3 times a day) to 48 patients with diabetes for 3 months. They found that berberine decreased fasting and post meal blood glucose levels after 1 week. They also found that the patients’ insulin resistance decreased to 45% (99). A meta-analysis on 14 studies involving 1068 participants has revealed that berberine effects are similar to those of metformin, glipizide, and rosiglitazone. These drugs are the most important diabetes drugs on the market (100). Most importantly, berberine has no serious side effects. Table 5 demonstrates recent clinical trials testing berberine with respect to diabetic and inflammatory markers.

Genistein

The isoflavone genistein is a naturally occurring phytoestrogen, which is particularly highly concentrated in soy and soy-derived products; its possible suitability as a pharmacological agent has been studied, as it has been illustrated that people in Asia consuming large amounts of genistein-rich soy products are seldom affected by prostate or breast cancer (104, 105) and Type 2 diabetes (106). In hypoxic conditions, genistein has been shown to suppress the HIF1α expression, accumulation, and activation of ERK (107, 108). Also, genistein seems to provide a protective effect on myocardial and endothelial cells, as it activates the exocytosis of the cardioprotective neuropeptide calcitonin gene-related peptide. This is due to vanillin receptor 1(VR1)-mediated action, of which genistein is supposed to be a direct activator (109), apart from capsaicin and gingerol. In adipocytes, genistein acts as an anti-inflammatory substance, down-regulates leptin production in the presence of 50 μM(110), induces apoptosis at 100 μM (111), and also counteracts the antilipolytic action of insulin if used at concentrations higher than 12.5 μM (112). This is probably due to PPARγ, to which genistein is a direct ligand and activator (113). However, the effect of genistein on differentiation of adipocytes has been illustrated with...

Ow: overweight; MetS: metabolic syndrome; T2DM: Type 2 diabetes mellitus; d: days; w: weeks; t.w.: together with; IL: interleukin; TNFα: tumor necrosis factor α; TAC: total antioxidant capacity; MDA: Malondialdehyde

Inconsistent results; this is in part due to contradictory actions of genistein with respect to applied concentrations (110, 111, 113-119). In a study, streptozotocin-diabetic rats that received a daily intraperitoneal injection of 1 mg/kg bw showed a hypoglycemic effect (120). In a study on mice, 2 and 4 g genistein/kg diet significantly decreased fat pads, cholesterol, and lipid levels. Moreover, it inhibited mRNA expression of PPARγ, leptin, and TNFα and also increased mRNA expression in case of PPARα, AMPK, and adiponectin in adipose tissue (121). Furthermore, it enhanced the expression of genes involved in fatty acid oxidation, and at the same time, activated expression of UCP2, which mediates proton leakage by uncoupling ATP synthesis. This lowered metabolic efficiency may also account for the reduced fat accumulation and weight gain in animals receiving a daily genistein dose of about 200, 400, or 800 mg/kg of the body weight (117). Similar to resveratrol, genistein administration decreased the ATP level in adipocytes (122). Recent clinical trials on genistein in males showed an increase in adiponectin levels and a decrease in cholesterol and insulin levels, with doses that can easily be obtained by a soy-rich diet. Table 6 displays recent clinical trials testing genistein with respect to diabetic and inflammatory markers.

Combined effects of natural products

http://mjiri.iums.ac.ir
Some studies propose that the anti-inflammatory and antidiabetic impacts of these natural products could be achieved even if fewer doses are used in combination. These combinations synergistically enhance their anti-inflammatory activity and the therapeutic effect on inflamed adipose tissue. Resveratrol and quercetin in combination activated caspase-3 in human pancreatic carcinoma cells (129), inhibited lipid accumulation, decreased the expression of PPARγ, and enhanced apoptosis in 3T3-L1 mouse adipocytes. The effect was more than the expected additive response (130). Another study demonstrated that genistein and resveratrol in combination have a more potent impact on inhibiting adipogenesis and stimulating apoptosis (at dose 100 µmol/L genistein +100 µmol/L resveratrol) and promoting lipolysis (at dose 25 µmol/L genistein +25 µmol/L resveratrol) in 3T3-L1 mouse preadipocytes and mature adipocytes than each of these compounds alone (131). It was also reported that the combined treatment of primary human adipocytes with low concentrations of genistein, quercetin, and resveratrol suppressed lipid aggregation in maturing adipocytes, decreased cell viability, and stimulated apoptosis, whereas the treatment of the compounds alone had no apoptosis inducing impact (132). Hence, possible toxic impacts could be prevented by decreasing the dosage of each single natural compound. In general, with respect to the data from clinical studies, a combination of several phytochemicals seems to exceed the effect of single administration. Thus, in patients with T2DM or other inflammatory diseases, a more comprehensive knowledge on reasonable combinations of the mentioned phytochemicals can be useful. Interestingly, many natural products contain a well-established combination of several phytochemicals like green tea, grapes, or other fruits, and vegetables. Table 7 shows recent clinical trials testing quercetin with respect to diabetic and inflammatory markers.

**Ginger (Zingiber Officinale Roscoe)**

The main pharmacological actions of ginger include immunomodulatory, antitumorogenes, antiinflammatory, antiapoptosis, and antiemetic. Ginger has different components such as gingerols, shogaols, paradols, gingerdiols, etc.

Ginger is the underground stem of the plant Zingiber Officinale and most likely originates from southern China. Gingerol has been identified as a major bioactive component. Moreover, 6-gingerol, with a concentration of about 1.3–1.9 mg/g ginger, is the most abundant component in the ginger extract, which has been known to have a strong anti-inflammatory activity (143, 144). Gingerols also possess immunosuppressive (145) and antitumor-promoting properties. They inhibit the expression of COX-2 through inhibiting p38 MAPK and NF-kB activation (146) and decrease TNF-α expression, inflammation, and tumor promotion after application to the skin of mice (5, 147). Also, it has recently been reported that 6-gingerol can upregulate HIF-1α during mouse embryogenesis and prevent developmental disorders in the context of hypoxia (148). However, PPARγ is not affected by gingerol, which contradicts other phytochemicals (149). Treatment of mouse adipocytes with gingerol increased differentiation and enhanced insulin sensitive and glucose uptake; hence, it is expected to improve the diabetic state as well (150). Moreover, 6-gingerol at concentrations of 10 and 25 µM was shown to have additional effect on the regulation of adipocyte function through inhibiting TNF-α-mediated decrease of adiponectin expression in mouse adipocytes via inhibiting JNK phosphorylation (149). Because of its structural homology to spice-derived compound capsaicin, gingerol is a further VR1 agonist (151), which might play a role in suppressing inflammatory responses of adipose tissue in obesity (152). In a study, animals that were fed a high-fat diet showed a significantly increased serum insulin concentration and better glucose tolerance if their diet was enriched with 2% ginger (153). In a similar study, the daily intra-peritoneal administration of raw ginger extract (500 mg/kg bw) significantly decreased serum glucose, tracycylglycerol, and cholesterol levels and reversed diabetic proteinuria (154). A recent in vivo study using high-fat fed mice showed that after adding 0.05% 6-gingerol supplementation to the mice diet, their body weight gain and adiposity in association with a modified cholesterol metabolism and fatty acid oxidation significantly decreased (155). However, to obtain an equivalent content of 6-gingerol, consumption of about 2.5 g/day of fresh ginger rhizome per kg bw (a 30 g mouse consuming 3 g/day) is necessary. Also, the administration of a ginger extract to diabetic rats (200 mg/kg bw) reduced their blood glucose levels and affected intra and extramitochondrial enzyme activities (156).

These animal studies show that ginger possesses hypcholesterolemic, hypolipidemic, and hypoglycaemic potential, and thus may be of value in humans. There are only few recent clinical trials focusing on the applicability of gingerol for the treatment of diabetes or related purposes in humans. Recent studies have found that consuming gingerol with the doses between 100 mg and 3 g can lower eicosanoid and lipid levels (157). In Arablou et al. study, 70 diabetic patients were enrolled and consumed 1600 mg ginger versus 1600 mg wheat flour for 12 weeks; and they found that ginger decreased C-reactive protein and prostaglandin E2 (significantly), fasting plasma glucose, hemoglobin A1C, insulin, and HOMA index compared to placebo group. However, there were no significant differences in tumor necrosis factor α between the 2 groups (158). In another study, Mahluji et al. found that taking 2 g of ginger per day for 2 months has no effect on FPG and HbA1C, but can decrease serum insulin and HOMA. This difference is attributable to longer duration of study (159). Bordia et al. observed no significant changes in blood sugar levels in healthy individuals and patients with CAD and Type 2 diabetes with or without CAD after receiving 3g ginger for 3 months (160). Thus, ginger can probably reduce C-reactive protein, prostaglandin E2, blood glucose, insulin levels, and improve insulin sensitivity patients with

Type 2 diabetes. Table 8 displays recent clinical trials testing ginger with respect to diabetic and inflammatory markers.

Effect of phytochemicals on adipose tissue inflammation and diabetes

Adipocytes are the place for energy storage and they produce cytokines including interleukin IL-1β, IL-6, TNF-α, MCP-1, leptin, adiponectin, and many other molecules; thereby, they are referred to as adipokines. In the context of inflammation, the adipose tissue is infiltrated through macrophages, and it also releases proinflammatory mediators, produces reactive oxygen species, and stimulates T-cell responses for successful defense against invading organisms.

Hypoxia

Obesity decreases tissue mass access to oxygen (166-169). In mitochondria, reactive oxygen species (ROS) production elevates because of hypoxia (170), and consequently, compensatory angiogenesis is induced. This action leads to a reduction of adiponectin expression and secretion and an increase of proangiogenic genes including leptin, IL-6, and the vascular endothelial growth factor (VEGF) by adipocytes (171). It also stimulates expression of IL1β, IL-6, and TNF-α in macrophages (172). Hence, hypoxia is another key player with the potential to activate such inflammatory cascades in adipose tissue. Evidence for this hypothesis was provided previously when it was shown that hypoxia occurs in the adipose tissue of different obese mouse models and contributes to the endocrine dysregulation (172-174). However, it is unclear whether hypoxia in adipocytes triggers the inflammatory cascade per se without interfering with immune cells or other parameters.

Immune cells are known to invade adipose tissue. In adipose tissue, the interaction of immune cells with adjacent adipocytes increases the inflammation. These cells may also directly express expression of proinflammatory genes by hypoxia (174-182). Some polyphenols as resveratrol, quercetin, and catechins are present at higher concentrations in red grapes. The balance of consumed versus stored energy is represented through the AMP; ATP ratio can be assessed by the AMPK, which plays a central role in the regulation of glucose and lipid metabolism. Its overactivation by high AMP and low ATP levels, respectively, enhances cellular energy levels through suppressing anabolic energy consuming pathways (synthesis of lipids, glucose, and protein) and stimulating energy producing catabolic pathways (the uptake and oxidation of glucose and fat).

One of the important polyphenols mechanisms of action is the activation of PPAR-γ, which has regulatory effects on metabolism and inflammatory processes. PPARγ is restricted largely to adipose tissue and, to a much lesser extent, to immune cells. It is an activator of adipogenesis, as it induces fatty acid synthesis and storage, and thus it is likely inhibited by AMPK (18, 183, 184). Also, PPARγ represses the expression of inflammatory genes as iNOS suppresses transcription factors AP-1 and NF-κB, modulates MAPK activity, and influences glucose uptake (185). Hence, PPARγ is a suitable target for medical intervention, and PPARγ-activating pioglitazone is a well-known antidiabetic drug for treatment of T2DM (186).

These pathways are activated in adipose tissue. Also, JNK is activated by insulin but mediates feedback inhibition of insulin signaling, and thus contributes to insulin resistance (187). The insulin/IGF-1 signaling plays a role in developing cancer and T2DM (188). Sugar-rich food in Western diet induces insulin. The resulting insulin/IGF-1 signaling (IIS) activates the phosphatidylinositol 3-kinase (PI3K) and Akt kinase that mediate the suppression of transcription factors of the Forkhead box O (FoxO)(189), which are supposed to prevent uncontrolled inflammatory response (190), indicating a link between Western diet and development of civilization diseases like cancers and T2DM (188).

Conclusion

In this review, we discussed the effects of polyphenols on blood glucose and diabetes complications and mechanisms of their actions. To answer these questions, we focused on specific food sources rich in dietary polyphenols.
Interaction of phytochemicals with receptor PPARγ has been shown to affect AMPK or NRF-2, which are involved in the regulation of glucose metabolism and energy production. Resveratrol, genistein, curcumin, and quercetin interact with these pathways, leading to the activation of PPARγ and NRF-2. This interaction is mediated by the activation of transcription factors such as the nuclear factor κB (NF-κB) and the c-Jun N-terminal kinase (JNK) pathway, which are involved in the regulation of gene expression and the activation of inflammatory cascades via proteasomal activation and the subsequent activation of the inflammatory response.

Comparison of traditionally produced food to modern food, highlighting the potential benefits of polyphenols as antioxidants, has a beneficial role in improving health outcomes. Traditionally produced food, such as fruits, vegetables, and whole grains, contain polyphenols that have been shown to inhibit the respiratory chain and subsequent activation of the mitochondrial electron transport chain and the subsequent activation of the respiratory chain and ATP synthetase at the inner mitochondrial membrane (25, 114). Overproduction of ROS via the mitochondrial electron transfer chain is the link between several independent molecular mechanisms (AGE formation, the polyol and hexosamine pathway flux, PKC activation and NF-kB activation) implicated in diabetic side effects (194). Considering the central role of reactive oxygen substances (ROS) in disease states, the hypoxia-induced ROS production at the mitochondrial electron transport chain and the subsequent activation of the inflammatory response, it can be stated that polyphenols, as antioxidants, have a beneficial role in improving diabetes side effects (170). Furthermore, comparing traditionally produced food to modern food, phytochemicals may have probably been produced formerly in plants to a much higher amount than in today's industrialized and standardized agriculture. Because of a lack of stress via pathogens or pests, there may be better bioavailability and rapid metabolism of polyphenols.

Conflict of Interests
The authors declare that they have no competing interests.
