Abstract

**Background:** Thalassemia major (TM) is a severe disease and the most common anemia worldwide. The survival time of the disease and its risk factors are of importance for physicians. The present study was conducted to apply the semi-parametric Cox PH model and use parametric proportional hazards (PH) and accelerated failure time (AFT) models to identify the risk factors related to survival of TM patients.

**Methods:** The data of this historical cohort study (296 patients with TM) were collected during 1994 and 2013 in Zafar Clinic in Tehran. Gompertz PH and Weibull AFT models were used for survival analysis (SA) of these patients. Data analysis was performed using R3.2.2 software.

**Results:** 153 (51.7%) of patients were female; the mean (±SD) age of the patients was 29.11 (±0.47) years. One-year survival rate for males and females was 0.963±0.007 and 0.973±0.013, respectively; and 3-year survival rate for males and females was 0.711±0.057 and 0.733±0.114, respectively. In the Gompertz model, birthplace and age at onset of the disease were significant factors (p= 0.035, and p= 0.005) in survival time. Also, in the Weibull model, birth place and age at onset of the disease were significant factors (p= 0.013, and p= 0.008) in survival time. The Akaike Information Criterion (AIC) for Weibull model was 158.51, which was lower than other parametric models.

**Conclusion:** According to the results, the Weibull AFT model was found to be a better model for identifying the risk factors related to survival of patients with TM disease. Informing parents, especially mothers and paying attention to blood screening for early diagnosis may increase the survival rate of patients.

Introduction

Thalassemia is the most common inherited anemia in the world and also in Iran (1, 2). Middle Eastern countries have a high concentration of thalassemia (2). Moreover, 18 000 deaths occurred due to thalassemia major (TM) in 2010 (3). It has been reported that 5.2% of the world population are carriers of such disorders (4) and also the prevalence rate of thalassemia carriers is 4.5% in Iran (5). In addition, it has been reported that approximately 300 children with TM are born in Iran and also over 264 000 affected infants are born annually in developing countries.
Survival analysis of the thalassemia major patients

The thalassemia program was implemented in 1997 in Iran and aimed at reducing and preventing this disease (5, 6). Identifying the risk factors that affect the survival rate of TM patients is highly important for physicians and healthcare systems.

In this regard, survival analysis (SA) can be used to identify the risk factors for survival of patients (2, 6). This analysis, ie, SA, is a collection of statistical methods that involves the modeling of time to event data and is used to predict the occurrence and timing of events (7). In SA, which typically focuses on time to event data, there are different models to analyze survival times of data based on a set of predictor variables (7, 8), such as proportional hazard (PH) and accelerated failure time (AFT) models (7, 9). In the previous decades, data analysts have used various survival methods to determine prognostic factors and survival rate of TM patients (1, 2, 6, 10-16). The Cox PH model is one of the most popular semi-parametric methods used to predict survival of TM patients (7). The Weibull AFT model is a parametric method which can be used to predict the survival of TM patients. This model is more general than other parametric models (7, 8).

The most popular method for regression analysis of survival data is Cox regression, which combines the proportional hazards model with the partial likelihood method of estimation. It does not make specific assumptions about the probability distribution of event times. By contrast, parametric regression models assume particular families of probability distributions, such as exponential, Weibull, Gompertz, lognormal, log-logistic, or gamma (7, 9, 17).

However, it is of paramount importance to identify the prognostic factors affecting the long-term survival rate of TM patients. This study aimed at applying semi-parametric Cox PH model and a parametric PH and AFT model to identify the risk factors of TM patients.

Methods

Patient population

This historical cohort study was conducted by enrolling 296 TM patients. These patients had been referred to Zafar Thalassemia Clinic in Tehran during 1994 and 2013. This study was approved by the ethical committee of University of Social Welfare and Rehabilitation Sciences (IR.USWR.REC.1395.5).

Data collection

Data of all patients were collected based on patients’ medical records, and the collected data included the following information: sex, birth place (near the sea/not), date of birth (after 1997/before 1997), age at onset of disease, age of Desferal injection, age of transfused blood, splenectomy (no/yes), maternal education (no/yes), and consanguinity (no/yes). The survival time of each patient, in year, was defined as the interval between the date of birth and the date of death or date of follow-up time in May 2013 (the end of the study).

Statistical analyses

Cumulative survival rates were estimated using the Kaplan-Meier method. The log-rank test was used to compare the survival curves across the subgroups. A multivariate (adjusted analysis) Cox proportional hazards model was utilized to identify risk factors relating to survival of patients. Finally, parametric Gompertz PH and Weibull AFT model were used to determine the SA of TM patients. The Akaike information criterion (AIC) was utilized to compare these parametric models. The smaller value for this criterion means a better and more suitable model (7). All statistical analyses were performed using R 3.2.2 software. A $p<0.05$ was considered statistically significant.

AFT model

AFT model is a parametric model that assumes that the effect of a covariate is to accelerate or decelerate the survival (or the hazard) of a disease over time by some constant. For $i = 1, \ldots, n$, let $T_i$, $C_i$ and $X_i$ would be the failure time, censoring time, and the p×1 covariate vector for the i-th subject. It is assumed that $T_i$ is conditionally independent of $C_i$ given $X_i$. An univariate semiparametric AFT model has the form $\log(T_i) = X_i^T \beta + \varepsilon_i$, $i = 1, \ldots, n$, where $\beta$ is an unknown p×1 vector of regression parameter, $\varepsilon_i$'s are independent of $X_i$ and also independent, which is identically distributed in random variables with an unspecified distribution. Imagine that in i-th cluster, there is a random sample of n independent cluster with $K_i$ margin. In this case, the multivariate AFT model has the following form: $\log(T_{ik}) = X_{ik}^T \beta + \varepsilon_{ik}$ $i = 1, \ldots, n, k = 1, \ldots, K_i$. In the presence of censoring, the observed data would consist of copies of $(Y_{ik}, \Delta_{ik}, X_{ik})$, where $Y_{ik} = \min(T_{ik}, C_{ik})$ and $\Delta_{ik} = I(T_{ik} < C_{ik})$, and $I(\cdot)$ is the indicator function. Without censoring, the ordinary least square (OLS) method can be used to estimate all parameters. With censoring, one can use the Buckley-James estimator by adapting the OLS method (18-20).

Results

A total of 296 TM patients were included, with total time at risk, 2105.5 years. The minimum and maximum follow-up times were 5 and 49 months, respectively. Overall, 38 (12.84%) patients died. A total of 153 patients were female; and the mean±SD of patients’ age was 29.11±0.47 years. Overall, 2 patients had irregular blood transfusions, 141 (47.4%) had the sea birth place, 215 (72.6%) were born after 1997, 112 (37.8%) had splenectomy, and consanguinity was observed in 62 (21.6%) patients. In addition, 46 (15.6%) parents were illiterate. The mean (and median) ± SD of age at onset of disease, age of

| Table 1. One-, two-, and three- year survival probability of patients with TM using Kaplan-Meier method |
|----------------------------------------|--------|--------|
| Years                  | Women Total | Men Total  |
| One-year               | 0.969±0.010 | 0.973±0.013 | 0.963±0.007 |
| Two-year               | 0.882±0.021 | 0.902±0.028 | 0.856±0.033 |
| Three-year             | 0.728±0.046 | 0.733±0.114 | 0.711±0.057 |

Desferal injection and age of transfused blood was 2.31(0.83)±4.90, 5.79(4.00)±5.94, and 1.72(1.00)±2.82, respectively. 

Three-year survival rate for males and females was 0.711±0.057 and 0.733±0.114, respectively, based on Kaplan-Meier analysis (Table 1). The mean ± SD survival time of males and females was 41.75±1.46 and 37.43±0.76, respectively. The log-rank test revealed no difference between the mean survival time of males and females (X² = 3.197, df= 1, p= 0.074).

In the Cox proportional hazard model, age at onset of disease was a significant factor (p=0.040) in survival time (Table 2). In the Gompertz model, variables of birthplace and living near the sea were significant factors (p= 0.035 and p = 0.005, respectively) in survival time (Table 3). In the Weibull model, birthplace and age at onset of disease were significant variables (p= 0.013 and p= 0.008, respectively) in survival time (Table 4). The AIC for Weibull model was 158.51, which was lower than the Gompertz model (161.8). For this model, the hazard ratio (HR) estimate for age at onset of disease was exp (-0.246) = 0.782. Adjusted for other variables, this means that the age at onset of disease has a hazard rate of about 0.78 times on the hazard of the event, if 1 unit increased in the age at onset of disease. The hazard ratio estimate for birth place was exp (0.243)= 1.28, meaning that near the sea place of birth has a hazard rate of about 1.3 times more than birth at other places on the hazard of the event.

**Discussion**

A total of 81.5% of the TM patients survived in the study period, which is the overall median survival time that could not be calculated. However, the 1-year, 2-year, and 3-year survival rates of the patients were 97%, 88%, and 78%, respectively. On the other hand, TM patients had a high survival rate, and improvement in the survival rate of these patients was palpable. Previous studies in Iran showed that only 50% to 60% of beta-TM patients had long-term survival rate (2, 6, 10, 15).
Survival analysis of the thalassemia major patients

85%; moreover, education, marital status, ferritin levels, and comorbidities factors were related to survival rate of thalassemia patients (6). In another study, regular blood transfusion, blood screening, and family awareness affected the survival rate of these patients (10). The survival of those patients who were born after 1981 was better than the others (11). The 20-year survival rate of TM was reported to be 98.5%. Multivariate survival analysis revealed that female sex significantly affected the survival rate, but not the genotype, birth cohort (after 1974), or treatment center (12). Death of TM patients was reported to be 50% before the age of 35. Moreover, improved survival rate and survival without complication due to treatment was also reported (13, 14). The survival of TM patients was investigated and it was found that ethnicity and gender did not have any significant effects on the survival of these patients (1). Being alive until 20 years old was reported in 68% of TM patients and only half of them lived until 30 years old (15). The Cox regression model revealed that the interaction effect of sex and age was a risk factor for predicting mortality in patients (18). The expected survival probability of patients at 50 years was reported to be 0.63 (19). A study has reported better median survival time (4.89 yrs. for females and 3.84 yrs. for males) and better prognosis for females (20). The survival of both genders for birth cohort before and after 1986 was reported without any statistically significant differences. The survival rate of patients who were born after 1986 was reported to be better at 30 years old (68% vs. 80%) (21).

Conclusion
This study revealed that the variables of birth place, age at onset of disease, and age of transfused blood had significance effects on the survival of these patients. Unlike other studies, birth time of patients and gender did not significantly affect the survival of patients. One of the limitations of this study was missing values in explanatory variables. Based on the results, Weibull parametric model was selected as the best model. So, this model is suggested to other researchers. Furthermore, informing parents, especially mothers, and paying attention to blood screening to other researchers. Furthermore, informing parents, especially mothers, and paying attention to blood screening and family awareness affected the survival rate of these patients (10). The survival of those patients who were born after 1981 was better than the others (11). The 20-year survival rate of TM was reported to be 98.5%. Multivariate survival analysis revealed that female sex significantly affected the survival rate, but not the genotype, birth cohort (after 1974), or treatment center (12). Death of TM patients was reported to be 50% before the age of 35. Moreover, improved survival rate and survival without complication due to treatment was also reported (13, 14). The survival of TM patients was investigated and it was found that ethnicity and gender did not have any significant effects on the survival of these patients (1).
