ABSTRACT

Macrodystrophia lipomatosa is a rare congenital form of localized gigantism characterized by an increase in all mesenchymal elements, particularly fibroadipose tissue. MR imaging can be used to examine the soft tissue and detect the fibrous and fatty hypertrophy that characterizes this condition and also diagnose an associated fibrolipomatous hamartoma of the median or plantar nerve. We describe the clinical and radiological findings (including CT scan, MRI and bone scan) and also progression of this rare entity during a 10 year period.

Keywords: Macrodystrophia lipomatosa (MDL), Fibrolipomatous hamartoma (FLH). Magnetic resonance imaging, Computed tomography

INTRODUCTION

Macrodystrophia lipomatosa (MDL) is a rare disease typically causing localized gigantism of an extremity, usually the hand or foot, and is characterized by an increase in all mesenchymal elements, particularly fibroadipose tissue.

In the hands, it is often associated with FLH of the median nerve. Patients are generally asymptomatic, but seek a physician’s advice for cosmesis.

CASE REPORT

A 48-year-old right-hand-dominant woman presented with progressive enlargement & limitation of movement of her left second finger as her chief complaint since she was 10 years old. She had no pain or numbness. There was no family history of isolated extremity gigantism.

In physical examination, slight enlargement of the left arm and forearm was noted, the midhumeral circumference was 2cm larger than the right arm and there was great enlargement of the second and less so of the third finger with slight ulnar deviation (Fig. 1a).

No skin nodules, ulcer, pitting edema or cafe-au-lait spots were present. No audible bruits or thrills were heard at the elbow or wrist or fingers. Allen test was negative. The results of neurologic and vascular examinations were unremarkable.

The patient had lichen-planus type lesions on her lower limbs since last year, but after reviewing the literature there was no relation between these two entities and we considered these as coincidental findings.

A radiograph of the left hand showed soft tissue swelling containing mottled lucencies around the second and to a lesser degree the third digit. No soft tissue or vascular calcification was seen. There was enlargement of the bony parts of all phalanges in the 2nd & 3rd fingers and to a lesser degree in the 2nd metacarpal with a preserved trabecular pattern, also osteochondromatose-like projections were present near the IP (interphalangeal) joints with extensive secondary DJD changes in the IP joints (Fig. 1b). Slow progression of these changes during the last 10 years, in comparison of the X-rays, was obvious (Fig. 1c), and in skeletal survey, no other bony changes of this type were noted.

In whole body isotope scan with Tc99, slight increased activity was observed in the left hand, over the second finger and metacarpal, corresponding to increased activity of mesenchymal elements (Fig. 2).

CT scan of the left upper limb was performed with a

Fig. 1b. Radiograph of hands shows soft tissue swelling and mottled lucencies around the index and less involvement in the radial aspect of the middle finger. Exostosis-like projections and secondary DJD changes in IP joints are also noted.

spiral Toshiba CT scan, X vision, which showed asymmetric accumulation of adipose tissue (-100 Hu) in the 2nd & 3rd fingers, more in the tip of the finger than the base, and also in the wrist and less in lateral parts of the arm and forearm (Fig. 3a, b).

MR imaging performed with a G.E. 1.5T scanner showed asymmetric fat infiltration with similar intensity as subcutaneous fat without any obvious capsule or nerve involvement, including nerve hypertrophy or carpal tunnel syndrome, no medullary abnormality was identified (Fig. 4a, b).

Angiography was not performed, as it has been proven to be nonspecific.¹⁰

DISCUSSION

Macrodystrophia lipomatosa (MDL) was first described in 1925 by Friz.¹ It is a rare, unilateral, nonhereditary condition involving one or more digits of the extremities in distribution of the median nerve in the upper limb, or plantar nerve in the lower limb. Most often the middle and index fingers are involved.²⁻⁴

Most reported cases were present at birth and associated with a high incidence of anomalies including syndactyly, polydactyly, and clinodactyly.³ Digital overgrowth ceases at puberty with MDL and cosmesis is the primary reason for surgery.⁵

The differential diagnosis includes neurofibromatosis type I, hemangiomas, lymphangiomas, and Klippel-Trenaunay-Weber syndrome.¹⁵ In general, the clinical history and a thorough physical examination can help to distinguish these entities. Neurofibromatosis can be diagnosed by a positive family history and cutaneous cafe-au-lait spots. Bony changes in neurofibromatosis include thinned bone shafts and wavy cortices.⁴

Also a plexiform neurofibroma produces an enlarged,
