Abstract

Background: Iran reported its first COVID-19 deaths on February 19, 2020 and announced 1284 deaths with a laboratory-confirmed SARS-CoV-2 infection by March 19, 2020 (end of the winter 1398 SH). We estimated all-cause excess mortality, compared to the historical trends, to obtain an indirect estimate of COVID-19-related deaths.

Methods: We assembled time series of the seasonal number of all-cause mortalities from March 21, 2013 (spring of 1392 SH) to March 19, 2020 (winter 1398 SH) for each province of Iran and nationwide with the vital statistics data from the National Organization for Civil Registration (NOCR). We estimated the expected seasonal mortality and excess mortality (the difference between the number of registered and expected deaths). Moreover, we reviewed the provincial number of confirmed cases of COVID-19 to assess their association with excess deaths.

Results: The results of our analysis showed around 7507 (95% CI: 3,350 – 11,664) and 5180 (95% CI: 1,023 – 9,337) all-cause excess mortality in fall and winter, respectively. There were 3778 excess deaths occurred in Qom, Gilan, Mazandaran, and Golestan provinces in the winter, all among the COVID-19 epicenters based on the number of confirmed cases.

Conclusion: We think most of the excess deaths in the winter were related to COVID-19. Also, we think the influenza epidemic might have been the main reason for the excess mortality in the fall and parts of excess deaths in the winter of 1398 SH. Moreover, a review of all available clinical and paraclinical records and through analyses of the surveillance data for severe acute respiratory infections (SARI) can help to obtain a more accurate estimate of COVID-19 mortality.

Introduction

A novel coronavirus, SARS-CoV-2, was first reported in December 2019 in Wuhan, China (1). The disease caused by this virus was named COVID-19 (2). The virus quickly spread in the world, and the World Health Organization (WHO) characterized COVID-19 as a pandemic on March 11, 2020 (3). The number of reported COVID-19

cases in each country is a function of the real number of cases, health system capacity to detect cases, and its transparency to report correct measures. The capacity of the health system for detecting cases is driven by different factors, such as availability and accessibility of diagnostic (and screening) tests and healthcare services, accuracy of

↑What is “already known” in this topic:

- In the winter 1398 SH (March 19, 2020), the Ministry of Health and Medical Education of Iran reported 1284 deaths in confirmed cases of COVID-19.
- Fatalities due to some other causes of deaths, such as traffic injuries, have changed during the COVID-19 epidemic.

→What this article adds:

- Compared to the historical trend, 7507 (95% CI: 3,350–11,664) and 5180 (95% CI: 1,023–9,337) excess deaths were estimated for the fall and winter 1398 SH, respectively.
- We believe most of the excess deaths in the winter were related to COVID-19, although the continuation of the influenza epidemic in the fall might have contributed to the excess deaths in the winter.

laboratory tests, and raising public awareness about the disease, and establishing a process for seeking care (4, 5). Due to the disastrous nature of this epidemic and the risk of collapse in the health system, many of the suspected COVID-19 cases with mild to moderate symptoms and asymptomatic individuals exposed to known cases were encouraged to self-isolate themselves at home, even in the high-income countries (6). Thus, the number of confirmed cases does not necessarily reflect the real number of cases.

On February 19, 2020, Iran reported 2 confirmed cases of COVID-19 for the first time (7, 8) and reported its first deaths due to COVID-19 on the same day (8, 9). By the end of the winter 1398 SH (March 19, 2020), the number of reported cases and deaths due to COVID-19 in Iran reached to 18 407 and 1284, respectively (10, 11). The Ministry of Health and Medical Education (MoHME) reports the number of deaths occurring in persons with laboratory-confirmed SARS-CoV-2 infection. However, every person who had died of COVID-19 was not suspected to have COVID-19, diagnostic testing was not available to every person who was suspected to have the disease, and many of those who got tested, had false-negative results. A report estimated the sensitivity of COVID-19 testing in Iran to be around 51.4% (95% CI: 49.6% – 53.1%) (12).

Death registration systems are facing several challenges, such as undercoverage, incompleteness, improper allocation of causes of deaths, a high percentage of garbage codes, and delays in registration. In the middle of an epidemic, the performance of a death registration system may be even worse than usual. For instance, diagnostic tests might not be available, or their results might not be ready before the disposal of deceased cases. Also, the healthcare staff might be overwhelmed with clinical care, which increases errors in the allocation of causes of deaths. However, the number of deaths is expected to be a more robust indicator of the spread of the disease compared to the number of incident cases.

An “unusual rate of death” in Iran in the fall 1398 SH (September 23, 2019 – December 21, 2019) and the winter 1398 SH (December 22, 2019 – March 19, 2020) was also noticed by other authors (13, 14). The aim of this study was to provide an estimate of the all-cause excess mortality (the excess number of observed deaths compared to the expected seasonal number based on the historical trends) in Iran in fall and winter of 1398 SH. Estimating all-cause excess mortality from the national vital statistics data may provide a good assessment of the burden of the epidemics on mortality (15, 16).

Methods

We assembled time series of the seasonal number of all-cause mortality from the spring 1392 SH (March 21, 2013) to the winter 1398 SH (March 19, 2020) for each province and nationwide using the vital statistics data from the National Organization for Civil Registration (NOCR) (17).

First, we estimated the expected number of deaths in the country for each season using these time series. We fitted a linear regression model with a term for secular trend and

terms for seasonal variations to the time series data. We detected extremely influential observations using the DFITS statistic (18) and fitted the model again to the data without those observations. Removing those artifacts was a necessary step to obtain a more accurate estimate of the baseline expected mortality (19).

Then, we estimated the excess deaths in the country and in each province for the seasons of 1398 SH (March 20, 2019 – March 19, 2020) with the observed number of deaths in the previous years. We used the model above and data from prior seasons to estimate the number of expected deaths in each season. Next, we calculated the difference between the estimate from our model and the number of deaths registered by NOCR in that season. We used the standard errors of the forecast to calculate confidence intervals. Similar approaches have been widely used to calculate excess all-cause mortality during pandemics (15, 20).

Excess mortality is considered statistically significant when 95% confidence interval does not include zero. In this study all analyses were performed using Stata version 15.1 (21).

We extracted the provincial number of persons with a laboratory-confirmed COVID-19 in the winter 1398 SH from the daily briefings of MoHME (22). Number of COVID-19 deaths is not publicly available at the provincial level; thus, we plotted the number of excess deaths in the winter in each province against the number of confirmed COVID-19 cases in that season in the province to assess any association.

To have an idea about the potential decline in the number of deaths due to other causes, we extracted the number of deaths due to traffic injuries from the periodical reports of the Iranian Legal Medicine Organization (ILMO) (23). In addition to annual reports, ILMO has reports on the number of deaths for specific months of each year, including the last month of winter in each Solar Hijri calendar year, which is compatible with March 20th/21st to March 19th/20th of the Georgian calendar.

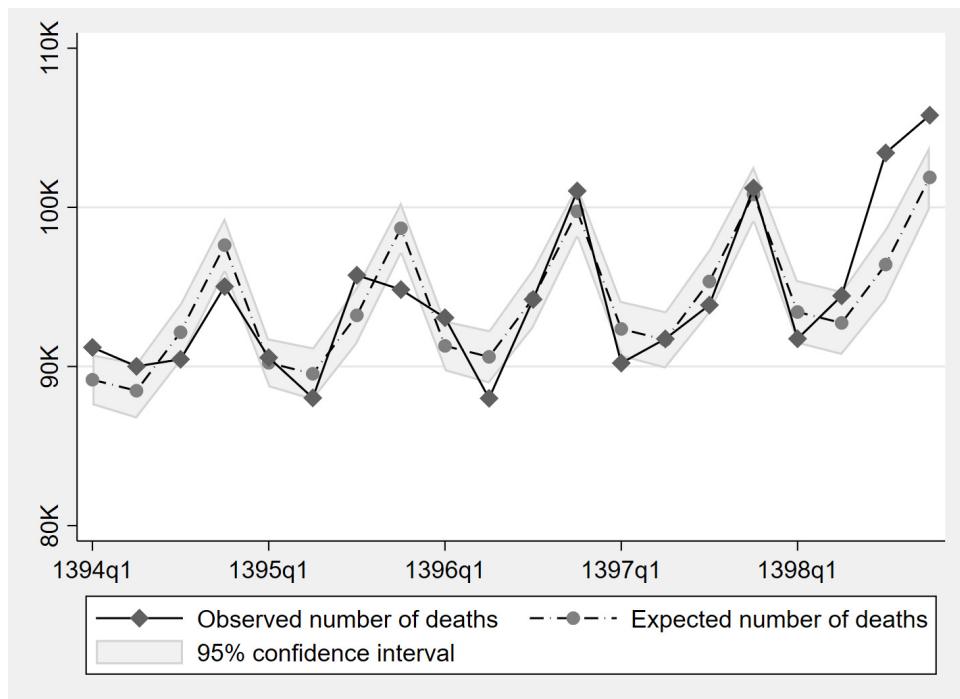

Results

In the year 1398 SH (March 20, 2019 – March 19, 2020), 395 392 deaths were registered by NOCR, which was 18 368 more than the previous year, 1397 SH (March 21, 2018 – March 19, 2019). The registered number of deaths in the spring and summer of 1398 SH was not significantly different from the expected numbers; however, the numbers of death tolls were beyond the expected numbers both in the fall and winter of 1398 SH (Fig. 1).

According to the NOCR, 103 422 deaths were registered in the fall season of 1398 SH in Iran, which was 9559 more than the fall 1397 SH, showing 7507 excess deaths (95% CI: 3350 – 11 664), compared to the expected baseline for the fall 1398 SH.

In our analysis by province, we found that 19 of 31 provinces had a significantly higher number of registered deaths in the fall 1398 SH compared to the expected baseline for that season. More details are available in Table 1.

According to the NOCR, 105 787 deaths were registered in the winter 1398 SH in Iran, which indicated 4577 more

Note: q1 refers to the spring season.

*: Count (percentage of excess deaths compared to total deaths); statistically significant differences, compared to the historical trends, are shown in bold.

deaths than the winter 1397 SH and 5180 excess deaths (95% CI: 1023 – 9337) compared to the expected baseline for the winter 1398 SH.

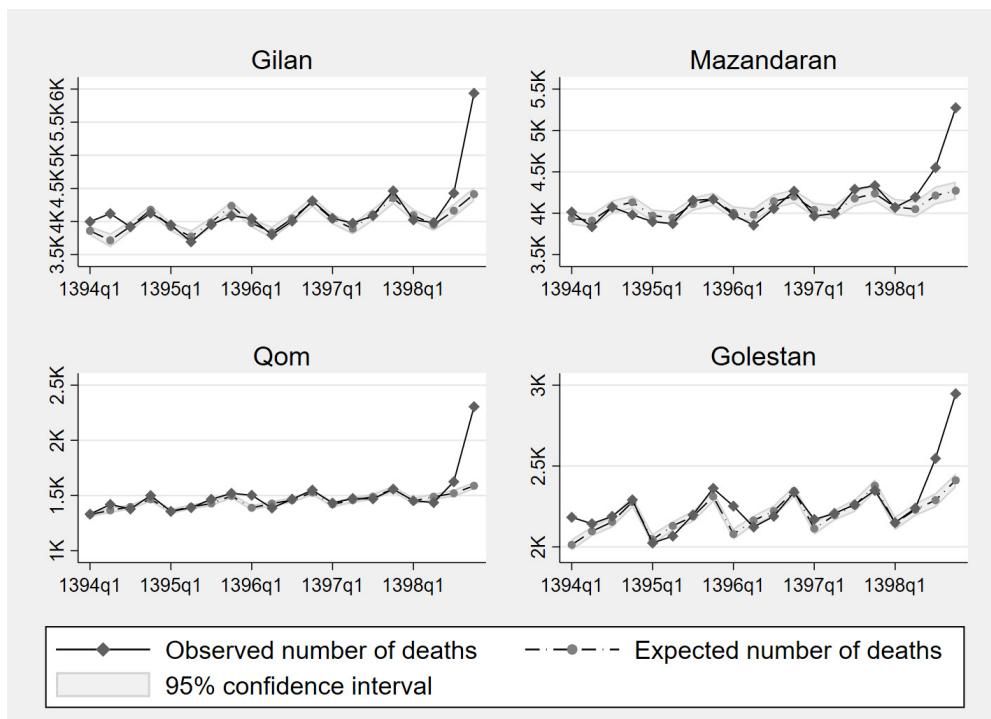

In our analysis by province, we found that 8 provinces had a significantly higher number of registered deaths in the winter 1398 SH compared to their expected baseline

for that season, and 1 province had a significantly lower number of registered deaths in the winter 1398 SH compared to its expected baseline for that season. Four leading provinces according to the percentage of excess deaths to total deaths were Qom, Gilan, Mazandaran, and Golestan (Fig. 2). The top 4 provinces according to the number of excess deaths were Gilan, Tehran, Mazandaran, and Qom.

The complete results are presented in Table 1.

The MoHME reported 1284 COVID-19 deaths in Iran until March 19, 2020 (10). The number of deaths due to COVID-19 by province was not officially reported. Figure 3 shows the association of estimated excess deaths and the number of COVID-19 confirmed cases.

The number of fatalities of traffic injuries in the last

Table 2 Deaths due to traffic injuries in the last month of the winter compared to the total number of registered deaths in the winter (1394-1398 SH, 2015-2020)

Solar Hijri* (Georgian) Year	Total Deaths in the Winter	Traffic Injury Deaths in the Last Month of the Winter	
		Number	Percent
1394 (2015-16)	95,026	1,280	1.35%
1395 (2016-17)	94,831	1,144	1.21%
1396 (2017-18)	101,030	1,179	1.17%
1397 (2018-19)	101,210	1,257	1.24%
1398 (2019-20)	105,787	1,048	0.99%

*: Each Solar Hijri year starts on March 20th/21st and ends on March 19th/20th of the next Georgian year

month of the winter and its percentage to the total number of deaths was lower in the winter 1398 SH compared to previous years in Iran (Table 2).

Discussion

We applied a regression model on the seasonal time series of all-cause deaths to estimate the excess mortality in the fall and winter of 1398 SH in Iran. The results of our analysis showed around 7507 and 5180 excess deaths in the fall and winter of 1398 SH in Iran, respectively. A total of 3778 excess deaths occurred in the winter only in the 4 provinces of Qom, Gilan, Mazandaran, and Golestan, with the highest rise in their mortality trajectories and all among the epicenters of COVID-19 in the winter. This number is remarkably higher than the 1284 confirmed COVID-19 deaths that were officially reported for the whole country in the winter.

The most common models use weekly or monthly data to estimate excess mortality, but such data were not available for this study. We used seasonal mortality data from NOCR, which reflects the number of deaths registered in each season. This means some deaths registered in every season may have occurred before that season. The United Nations Statistical Division (USDN) estimated the coverage of death registration in Iran to be around 92% (24). This indicator may vary among different subnational locations and periods. Due to partial closure of nonessential services, we expect to have more non-registered deaths or postponed registrations in the last month of the winter. Furthermore, we did not have access to age-specific mortality data for a more detailed and accurate estimation.

Some authors have earlier estimated the excess mortality in the fall and winter of 1398 SH in Iran by comparing the number of deaths with the 5-year average (13). That approach is more prone to overestimation due to neglecting the slight annual increase in the number of deaths, which is mainly due to population growth. We used a different approach for estimating excess deaths to address secular trends.

Considering the COVID-19 pandemic in the winter 2019-20, it is reasonable to assume that a major part of the excess deaths is due to COVID-19 or has been affected by the epidemic, and the association between excess deaths and the number of confirmed cases supports this argument. However, there are other potential causes for the difference between the expected and registered deaths. One of the potential causes is influenza; influenza is probably the main reason for excess deaths in the fall 1398 SH. The WHO had reported influenza activity “started to in-

crease” in Iran based on data from October 14, 2019 to October 27, 2019 (25), “continued to increase” based on data from October 28, 2019 to November 24, 2019 (26, 27), and “remained elevated” based on data from November 25, 2019 to December 22, 2019 (28, 29). Also, there were protests in November 2019 in some of the provinces of Iran (as a reaction to the rise of fuel price) that resulted in fatalities. Different numbers have been announced as the number of the death toll from around 200 to 230 (by a government official and a member of the parliament (30, 31)), to more than 304 (by the Amnesty International (32)) and 1500 (by a news agency (33)). Even with the highest current estimate of unrest fatalities, most of the fall 1398 SH excess deaths remain unexplained and are most likely to be due to the influenza epidemic. Assuming that most of the extra deaths in fall are due to the outbreak of influenza, then it is reasonable to assume that influenza has partially contributed to excess deaths in the winter 1398 SH as well. On the other hand, the number of fatalities due to traffic injuries was lower than expected, which might have been due to decreased transportation because of the COVID-19 interventions, or due to other factors not related to COVID-19 (such as the increased price of fuel or decreased general purchasing power). This factor, in addition to the potentially more than usual delayed registration of deaths at NOCR because of the social distancing interventions and partial closure of governmental organizations, may have contributed to an underestimation of excess deaths that are related to COVID-19. Experience of China (in Wuhan) shows that COVID-19 confirmed deaths might increase considerably after a retrograde comprehensive review of all clinical and paraclinical findings from different sources, such as hospitals and nursing homes (34).

Using the excess mortality has some limitations as a measure of the severity of epidemics; for instance, the number of NOCR registered deaths might change due to factors such as a change in regulations, which are completely irrelevant to health factors and the real number of deaths. There might be other reasons, not-related to COVID-19 or other factors mentioned in this report, which have contributed to excess mortality in the fall and winter of 1398 SH.

We did not have access to the provincial distribution of the number of confirmed COVID-19 deaths and surveillance data for severe acute respiratory infections (SARI); these are 2 important sources of data to assess excess deaths in the fall and winter of 1398 SH. Also, we did not have access to the age distribution of deaths in

each province; considering age and sex distributions might increase the accuracy of models for estimating expected deaths.

Conclusion

In the winter 1398 SH, Iran experienced around 5180 excess deaths compared to the expectations based on its historical trend. Although the extension of the influenza outbreak, which started in fall, might have contributed to the excess deaths of the winter, we think most of the excess mortality of the winter was related to COVID-19. Considering a decline in some other causes of deaths, such as traffic injuries, and an expected delay in vital registration due to epidemic situation, the real number of COVID-19-related deaths might be even higher. A second look and review of all clinical and paraclinical records and analysis of SARI findings can help to have a more accurate measure for the number of COVID-19-related deaths.
