School, Shiraz University of Medical Sciences, Shiraz, I.R. Iran.*

ABSTRACT

Argyrophilic nucleolar organizer regions (AgNORs) were determined in 94 pleural, pericardial and peritoneal effusions. The results were correlated with cytologic diagnosis to determine the diagnostic potential of this technique. Cytologically the number of normal, reactive and malignant effusions were 32, 28 and 34 respectively.

The mean AgNOR counts for normal, reactive and malignant specimens were 1.365, 2.328 and 4.747 respectively. The cut-off points between normal-reactive and reactive-malignant specimens were 1.84 and 3.53 respectively. All of the malignant specimens (100%) had AgNOR counts above 3.53.

Neither reactive nor normal specimens had AgNOR counts above 3.53. 82.1% of reactive specimens had AgNOR counts above 1.84 and 87.5% of normal specimens had AgNOR counts below this point.

There was a statistically significant difference between the AgNOR counts in normal, reactive and malignant effusions ($p < 0.001$).

We conclude that the AgNOR method is a specific diagnostic tool for serosal cavity effusions, especially when malignancy is suspected.

MJIRI, Vol. 16, No. 2, 95-100, 2002.

INTRODUCTION

Nucleolar organizer regions (NORs) represent loops of ribosomal DNA, located in the nucleoli of chromosomes 13,14,15, 21, and 22 which are responsible for the transcription of ribosomal RNA, the main protein synthesis region.^{1,2,17,29} Therefore it has been suggested that the number of NORs may reflect nuclear and cellular activity.^{1,17,23,29} NORs are argyrophilic because their associated acidic proteins (i.e., C₂₃, B₂₃ and possibly their RNA polymerase-I) contain abundant sulfhydryl and carboxy groups which precipitate silver ions.¹⁷ NORs can therefore be visualized as intranuclear black dots by his-

tochemical staining with a colloid silver solution.²⁹

Ploton et al. first modified the AgNOR technique for paraffin-embedded formalin fixed tissues.²⁷ Then Crocker and his colleagues reported the application of the AgNOR technique for diagnostic tumor pathology.

This method has been used for many types of benign and malignant lesions including breast,²⁹ colon,³⁴ cervix,⁴ endometrium,⁶ melanocytic skin lesions,²³ non-Hodgkin's lymphoma,²⁴ acute leukemia,²⁵ chordoma²⁸ and prostate.¹⁷

Ayres et al. were the first scientists who applied the AgNOR technique on paraffin-embedded mesothelial biopsy (pleura) specimens to differentiate malignant from normal and reactive mesothelial cells in 1988.²

The first application of this technique on human effusion for differentiating between malignant, normal and reactive mesothelial cells was performed by Derenzini et al. in 1989.¹⁵

AgNOR Staining of Serosal Body Fluids

Cytologic evaluation of serosal cavity effusions for malignancy is used routinely in the diagnosis, prognosis and therapeutic management of malignant neoplasms.^{9,35,36} Studies, however, have shown that such evaluation renders a high false negative rate.^{9,26,31}

In this study we have investigated the utility of the AgNOR technique as an adjunct to cytologic diagnosis in serosal effusions to differentiate between benign mesothelial cells, reactive mesothelial cells and malignant cells.

MATERIAL AND METHODS

Pleural, peritoneal and pericardial effusion slides were selected from the files of cytology departments of Shahid Beheshti, Nemazee and Shahid Faghihi hospitals, from 1980 to 1999. 94 specimens of those were selected and classified as metastatic carcinoma, reactive and normal. 34 cases were malignant, 15 of them from pleural effusions (5 of the breast, 4 of the GI tract, 1 of the endometrium, 3 of the lung and 2 of the thyroid), 18 from peritoneal fluids (12 of the GI tract, 1 of the pancreas, 4 of the ovaries and 1 of the liver) and one from pericardial effusion of a patient with metastatic adenocarcinoma of the GI tract.

28 cases were reactive effusions including 19 pleural, one pericardial and eight peritoneal fluids.

32 cases were from normal effusions including 17 pleural, one pericardial and 14 peritoneal fluids.

The AgNOR staining was performed on air dried smears.

The procedure was as follows:

A: Materials for AgNOR staining

- 1- Silver nitrate
- 2- Gelatin
- 3- Formic acid
- 4- 3:1 mixture of absolute ethanol: acetic acid
- 5- Deionized distilled water
- 6- Distilled water
- 7: Xylene

B: Making of AgNOR solution

AgNOR solution: 2 parts of solution A + 1 part of solution B

Solution A: 50% aqueous silver nitrate.

Solution B: 2g gelatin and 1mL formic acid in 100mL deionized distilled water.

C: Method of staining

Air-dried smears were fixed for 15 minutes in a 3:1 mixture of absolute ethanol: acetic acid and progressively rehydrated. The slides were then washed three times in deionized distilled water and placed in a freshly prepared

staining solution for 30 minutes at room temperature in the dark, dehydrated with xylene and then counted.

D: Method of AgNOR counting

In light microscopic examination, 200 random nuclei in each slide were counted, using a 100x oil-immersion objective and a 10 ocular. Only nuclei of mesothelial or epithelial cells were evaluated.

Inflammatory cells (PMNs, lymphocytes and macrophages) were excluded. All argyrophilic black dots in nucleolar and extranucleolar areas were counted and the mean was calculated in each case.

E: Pap and Wright stain

Before AgNOR staining and for confirming the previous results of pap and Wright methods, the pap and wright stained slides of each case were evaluated again.

F: Screening of cases

The pap and Wright stained slides with good preparation (staining and fixation) for the three groups of our study (normal, benign reactive and malignant) were selected.

We also considered that the number of mesothelial cells in normal and benign reactive groups be adequate for evaluation (>200). Then the counterpart air-dried slides for AgNOR staining were prepared.

G: Comparing of AgNOR with pap and Wright methods

After AgNOR staining, the mean number, distribution and size of AgNOR black dots on each nucleus were counted, evaluated and compared with the counterpart pap and Wright results.

RESULTS

Cytomorphologically 32 cases (34%) were normal, 28 (29.8%) reactive and 34 (36.2%) malignant. The mean ages for each group of normal, reactive and malignant effusions were 40.78, 54.07 and 54.87 years respectively.

The sex distribution in each group was as follows: Normal effusion: Female: 53.1%, Male: 46.9%; Reactive effusion: Female: 50%, Male: 50%; Malignant effusions: Female: 52.9%, Male: 47.1%.

Fig. 1. shows the abundance of different types of body effusions in each group. The total AgNOR counts in the 32 normal samples ranged from 0.7 to 2.1 (mean: 1.365 ± 0.378 SD) (Figs. 2-3). The range of AgNOR counts in the reactive effusions was from 1.2 to 3.1 (mean: 2.328 ± 0.502 SD) (Figs. 2-3). The range of AgNOR counts in malignant effusions was from 3.9 to 6.5 (mean: 4.747 ± 0.657 SD), (Fig. 2-3). The cut-off points between normal-reactive and reactive-malignant

Fig. 1. The abundance of different types of body effusions in three groups of normal, reactive and malignant patients.

A: Normal mesothelial cells
 B: Reactive mesothelial cells
 C: Malignant cells.

samples were 1.84 and 3.53 respectively. 34 (100%) of the malignant effusions had AgNOR counts above 3.53.

23 (82.1%) of the reactive samples had AgNOR counts above 1.84, and 5 (17.9%) of them showed overlapping with normal effusions. None of these samples had AgNOR counts above 3.53. 28 cases (87.5%) of normal effusions had AgNOR counts below 1.84 and 4 of them (12.5%) showed overlapping with reactive samples. None of these effusions had AgNOR counts above 3.53.

There was a statistically significant difference between the AgNOR counts in normal, reactive and malignant effusions ($p < 0.001$).

The AgNOR black dots were more irregularly distributed and variably sized in cancer cells than in reactive or normal mesothelial cells. (Figs. 4-7).

DISCUSSION

In cytologic preparations of serosal fluids, the diagnosis of malignancy is frequently difficult, because malignant cells frequently lose their in situ organization and their relationship with surrounding tissues that normally renders the nature of the lesion to be easily recognisable.

Indeed, it is not always possible to distinguish neoplastic cells from reactive mesothelial cells on purely morphologic grounds.¹⁵

Detection of proliferating cell nuclear antigen (PCNA) is a technique which can be used for differentiating carcinoma cells from reactive mesothelial cells. PCNA is a non-histone nuclear protein which is an auxiliary protein for DNA polymerase and a marker for cell proliferation.³

Many studies have reported the use of other immunocytochemical techniques to differentiate carcinoma cells from reactive mesothelial cells.^{18,19,33}

To solve this problem, many scientists have recently shown interest in the AgNOR technique.¹⁵ The silver-staining method used in the present investigation was initially used as a very simple method for visualizing the NORs in metaphase chromosomes^{20,21} (NORs are DNA loops encoding riboso-

mal RNA production).¹⁵

Many studies have demonstrated that silver-staining methods selectively stain acidic proteins (AgNOR proteins) associated with the ribosomal sequences. The application of silver staining for AgNOR proteins to interphase nuclei showed the localization of the ribosomal genes in the fibrillar components of the nucleolus (fibrillary centers and dense fibrillary component) which thus represent the interphase counterpart of metaphase NORs.^{20,21}

It has long been known that malignant cells have hypertrophic and irregular shaped nucleoli with irregular distribution of the nucleolar components.^{7,8,22} These morphologic abnormalities can be quantified using the distribution of interphase NORs in nucleoli as a parameter.^{14,15}

AgNOR staining was first applied to distinguish benign nevi from melanoma and then to distinguish other benign from malignant lesions.^{12,13} Many authors believe that an increased number of interphase NORs is a good clue to differentiate malignant from benign cells. In addition to an increased number of NORs, malignant cells were characterized by irregularly scattered and heterogen sized NORs. This may also help for differentiation between benign and malignant cells.

Studies on body effusions showed a significant difference in AgNOR numbers between malignant cells (mesothelial versus non-mesothelial), normal and reactive mesothelial cells.^{3,9,10,11,15,30,32}

Our study shows that the interphasic NOR distribution pattern permits a clear distinction to be made between neoplastic cells, benign reactive and normal mesothelial cells in human effusions.

NORs in neoplastic cells are very numerous and have heterogeneity in size and irregular distribution throughout the nucleus.

Reactive mesothelial cells have a more regular distribution of the NORs than neoplastic cells and significantly less numbers of AgNOR dots than neoplastic cells.

In these three groups (normal, benign reactive and malignant) the normal mesothelial cells have the least AgNOR counts with uniformly sized, small black dots. The difference between normal, reactive mesothelial and neoplastic NORs was also demonstrated by a quantitative analysis of the mean NOR areas.

Therefore, the different quantity of interphasic NORs in normal, reactive mesothelial cells and metastatic neoplastic cells might be explained by different proliferative rates of these cells.

The present study indicates that silver-staining for AgNOR proteins should be used routinely in diagnostic cytology. Also this reliable method gives information about the NOR distribution pattern that permits a diagnosis of malignancy even if the tumor cells represent only a small portion of all cells in the effusion.
